DIGITAL HUMANITIES

What makes Bach sound like Bach?

The composer Johann Sebastian Bach left behind an incomplete fugue upon his death, either as an unfinished work or perhaps as a puzzle for future composers to solve

The Art of Fugue is based on a single subject employed in some variation in each canon and fugue

- **Simple fugues** (Contrapunctus I-IV, 4 voices)
- **Counter fugues** subject used simultaneously in regular, inverted, augmented, and diminished forms (Contrapunctus V- VII)
- **Double and triple fugue**s, employing two and three subjects respectively (Contrapunctus VIII – XI)
- **Mirror fugues**, a piece is notated once and then with voices and counterpoint completely inverted, without violating contrapuntal rules or musicality (Contrapunctus XII – XIII)
- **Canons**, labelled by interval and technique (Augmentationem in Contrario Motu, alla Ottava, Decima in Contrapunto alla Terza, Duodecima in Contrapunto alla Quinta)

http://www.washington.edu/news/2016/11/30/what-makes-bach-sound-like-bach-new-dataset-teaches-algorithms-classical-music/

. . . UNFINISHED FUGUE

Fuga a 3 Soggetti (Contrapunctus XIV):

- 4-voice triple fugue
- the third subject of which is based on the B A C H motif

« At the point where the composer introduces the name BACH in the countersubject to this fugue, the composer died. »

THE CLOUD

Software as a service
PaaS

Platform as a service
PaaS

Infrastructure as a service
IaaS

- Illusion of infinite resources
- No up-front cost
- Fine-grained billing (e.g. hourly)

Promotes a style of computing in which dynamically scalable and often virtualized resources are provided as a service over the Internet

PaaS: allows customers to rent computers (virtual machines) on which to run their own computer applications.

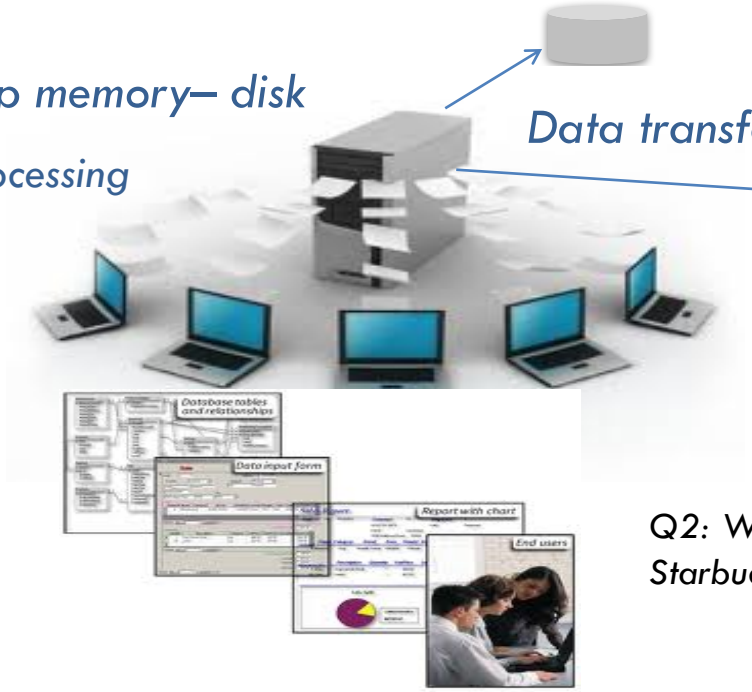
. . . WITH RESOURCES CONSTRAINTS

Distribution and organization of data on disk

Swap memory– disk

Data transfer

Query and data processing on server



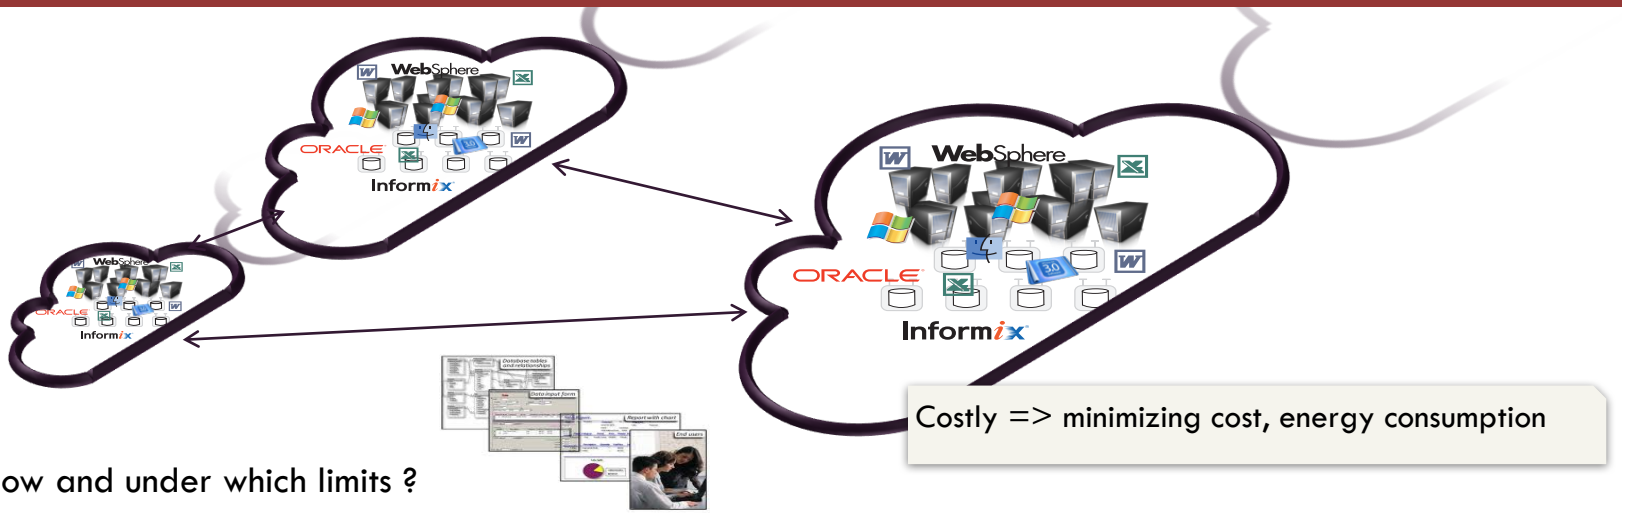
- Efficiency => time cost
- Optimizing memory and computing cost

Q2: Which are the consumption rules of Starbucks clients ?

Q1: Which are the most popular products at Starbucks ?

Efficiently manage and exploit data sets according to given specific storage, memory and computation resources

WITHOUT RESOURCES CONSTRAINTS . . .



- Query evaluation→ How and under which limits ?
- is not longer completely constraint by resources availability: computing, RAM, storage, network services
- Decision making process determined by resources consumption and consumer requirements

Data involved in the query, particularly in the result can have different costs: top 5 gratis and the rest available in return to a credit card number

Results storage and exploitation demands more resources

Reduce the cost to manage and exploit data sets according to unlimited storage, memory and computation resources

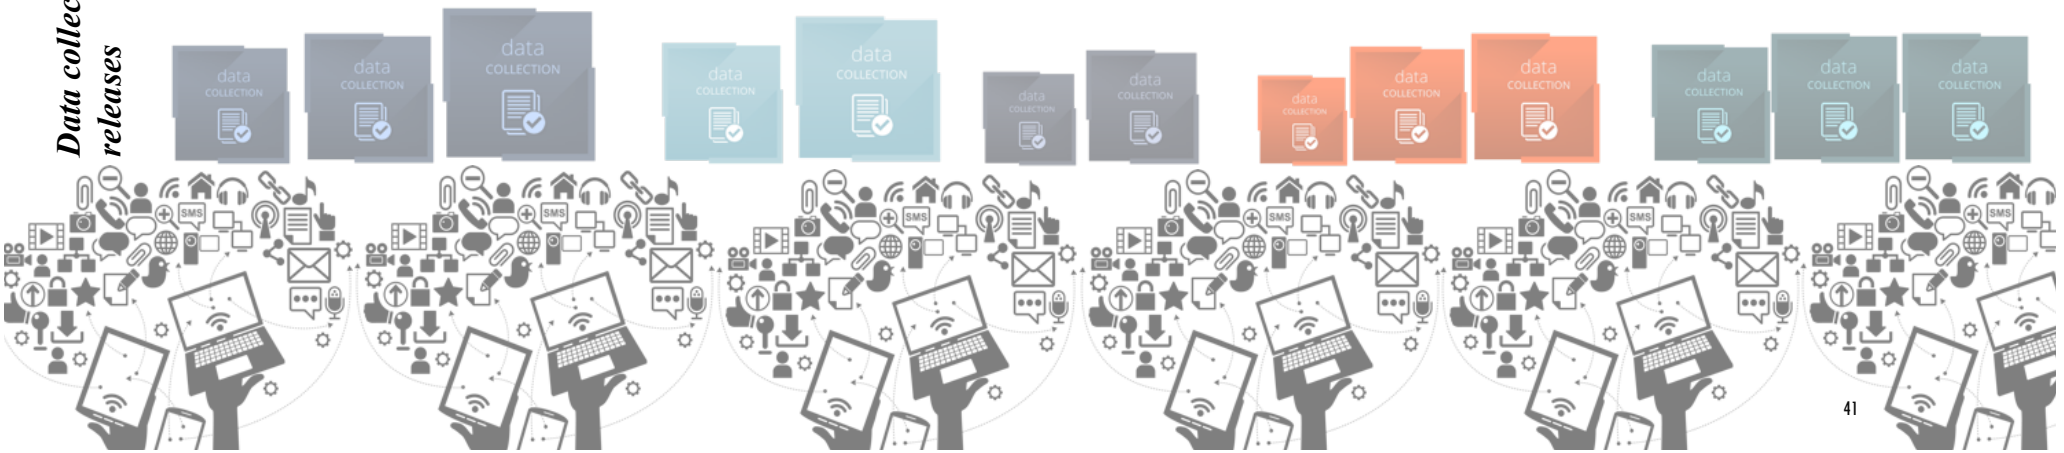
Applications & Data consumers

Data cleaning, processing and storage requires a lot of
DECISION MAKING

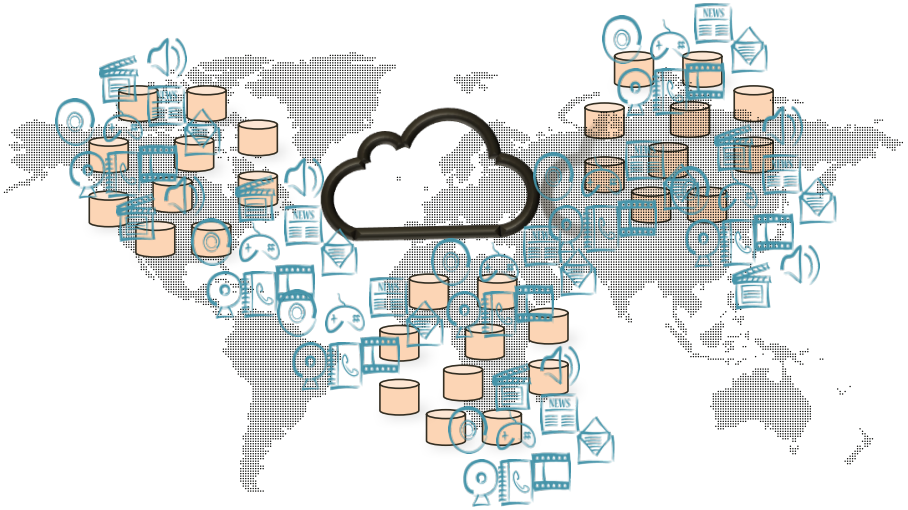
Data scientist requires **knowledge** about data collections content

Data collections' releases



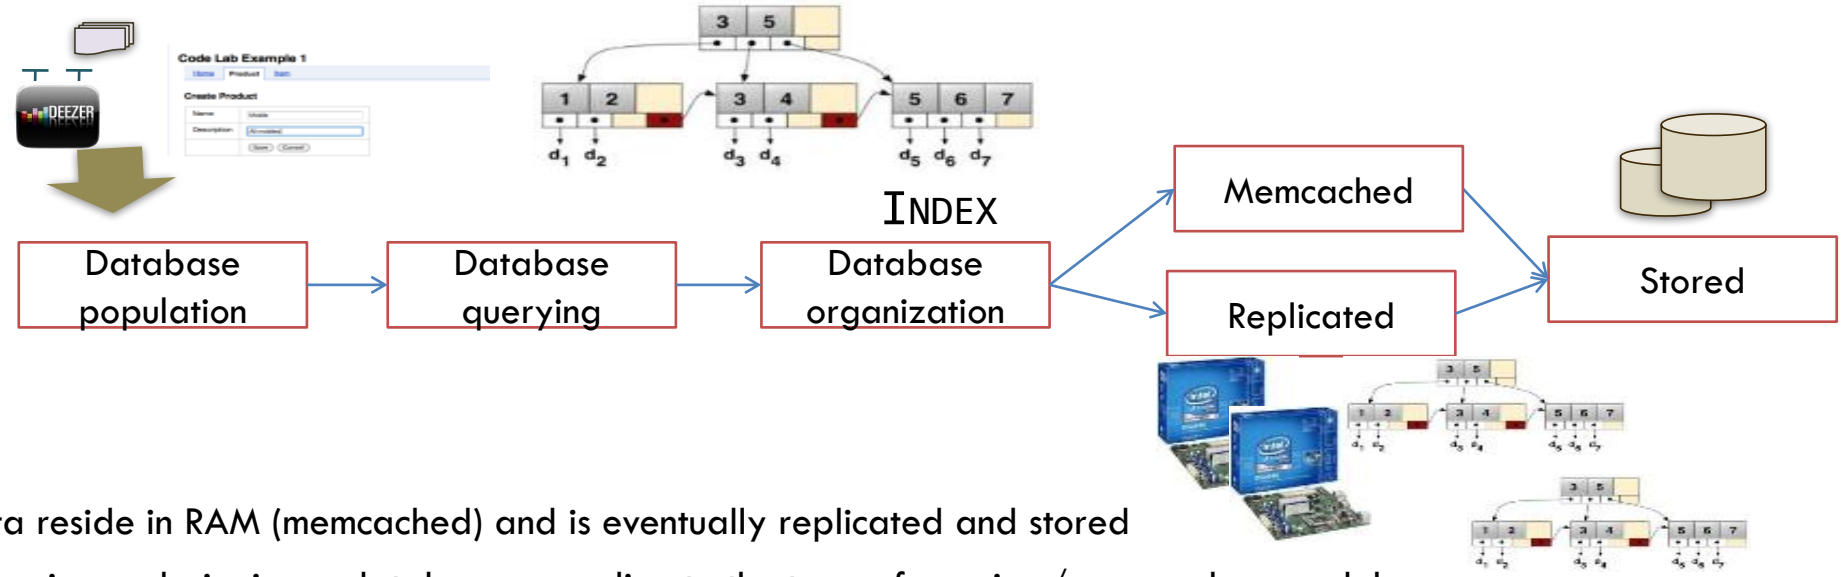
SCALING DATABASE SYSTEMS

- A system is scalable if increasing its resources (CPU, memory, disk) results in **increased performance** proportionally to the added resources
- Improving performance means serving more units of work for handling larger units of work like when data sets grow
- Database systems have been scaled by buying bigger faster and more expensive machines



- Vertically (SCALE UP)
  - Add resources (CPU, memory) to a single node in a system
- Horizontally (SCALE OUT)
  - Add more nodes to a system

NOSQL DESIGN AND CONSTRUCTION PROCESS



Data reside in RAM (memcached) and is eventually replicated and stored

Querying = designing a database according to the type of queries / map reduce model

"On demand" data management: the database is virtually organized per view (external schema) on cache and some view are made persistent

An elastic easy to evolve and explicitly configurable architecture

« MEMCHACHED »

«*memcached*» is a memory management protocol based on a cache:

- Uses the key-value notion
- Information is completly stored in RAM

«*memcached*» protocol for:

- Creating, retrieving, updating, and deleting information from the database
- Applications with their own «*memcached*» manager (Google, Facebook, YouTube, FarmVille, Twitter, Wikipedia)

PROBLEM STATEMENT: HOW MUCH TO GIVE UP?

Strict
The changes to the data are atomic and appear to take effect instantaneously. This is the highest form of consistency.

Sequential
Every client sees all changes in the same order they were applied.

Causal
All changes that are causally related are observed in the same order by all clients.

Eventual
When no updates occur for a period of time, eventually all updates will propagate through the system and all replicas will be consistent.

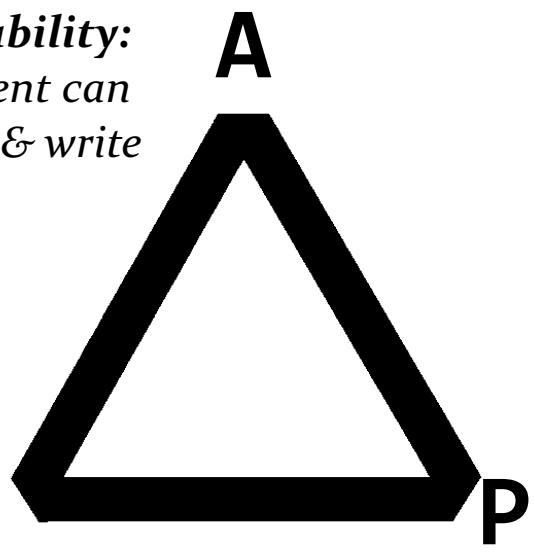
Weak
No guarantee is made that all updates will propagate and changes may appear out of order to various clients.

CAP theorem[1]: a system can have two of the three properties

NoSQL systems sacrifice **consistency**

1 Eric Brewer, "Towards robust distributed systems." PODC. 2000 http://www.cs.berkeley.edu/~brewer/cs262b-2004/PODC-keynote.pdf

VISUAL GUIDE TO NOSQL SYSTEMS



Availability:
each client can always read & write

C - A

- RDBM's
- MySQL
- Postgres
- etc
- Aster Data
- GreenPlum
- Vertica

Consistency:
all clients always have the same view of de data

C - P

- BigTable
- HyperTable
- Hbase
- MongoDB
- TerraStore
- Scalaris

A - P

- Dynamo
- Voldemort
- Tokyo Cabinet
- KAI
- Cassandra
- SimpleDB
- CouchDB
- Riak

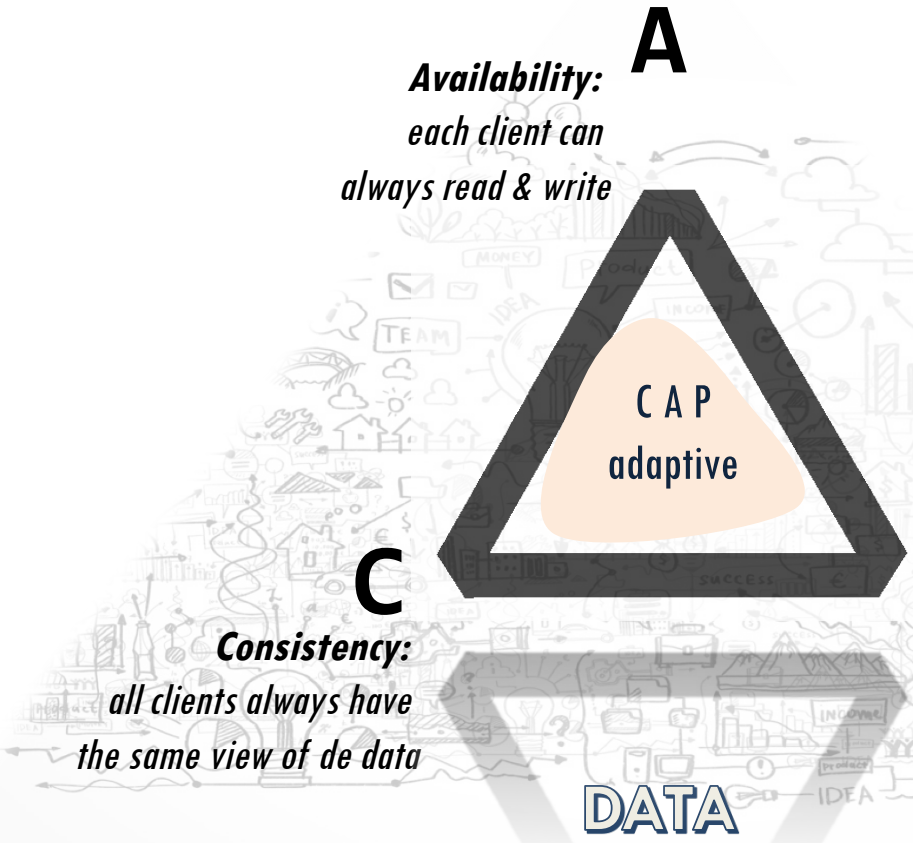
Partition tolerance:
The system works well despite physical network partitions

- BerkeleyDB
- MemcacheDB
- Redis

Data models

- Relational
- Key-Value
- Column oriented Tabular
- Document oriented

EFFICIENT R/W OF FRAGMENTED AND DISTRIBUTED DATA



Requirements

Operations

Hardware

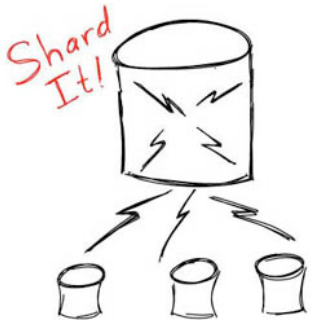
NOSQL STORES: AVAILABILITY & PERFORMANCE

Replication

- Copy data across multiple servers (each bit of data can be found in multiple servers)
- Increase data availability
- Faster query evaluation

Sharding

- Distribute different data across multiple servers
- Each server acts as the single source of a data subset



Orthogonal techniques

REPLICATION: PROS & CONS

Data is more available

- Failure of a site containing E does not result in unavailability of E if replicas exist

Performance

- Parallelism: queries processed in parallel on several nodes
- Reduce data transfer for local data

Increased updates cost

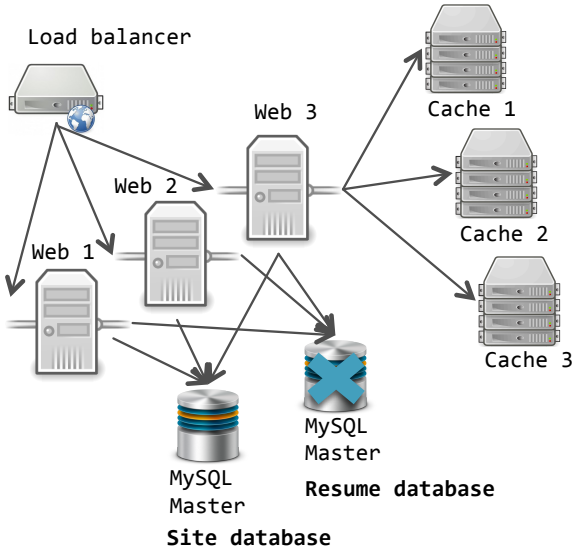
- Synchronisation: each replica must be updated

Increased complexity of concurrency control

- Concurrent updates to distinct replicas may lead to inconsistent data unless special concurrency control mechanisms are implemented

SHARDING: WHY IS IT USEFUL?

- Scaling applications by reducing data sets in any single databases
- Segregating data
- Sharing application data
- Securing sensitive data by isolating it



Improve read and write performance

- Smaller amount of data in each user group implies faster querying
- Isolating data into smaller shards accessed data is more likely to stay on cache
- More write bandwidth: writing can be done in parallel
- Smaller data sets are easier to backup, restore and manage

Massively work done

- Parallel work: scale out across more nodes
- Parallel backend: handling higher user loads
- Share nothing: very few bottlenecks

Decrease resilience improve availability

- If a box goes down others still operate
- But: Part of the data missing

SHARDING & REPLICATION

Sharding with no replication: unique copy, distributed data sets

- (+) Better concurrency levels (shards are accessed independently)
- (-) Cost of checking constraints, rebuilding aggregates
- Ensure that queries and updates are distributed across shards

Replication of shards

- (+) Query performance (availability)
- (-) Cost of updating, of checking constraints, complexity of concurrency control

Partial replication (most of the times)

- Only some shards are duplicated

SHARDING STRATEGIES USING MONGODB

MONGODB SHARDING

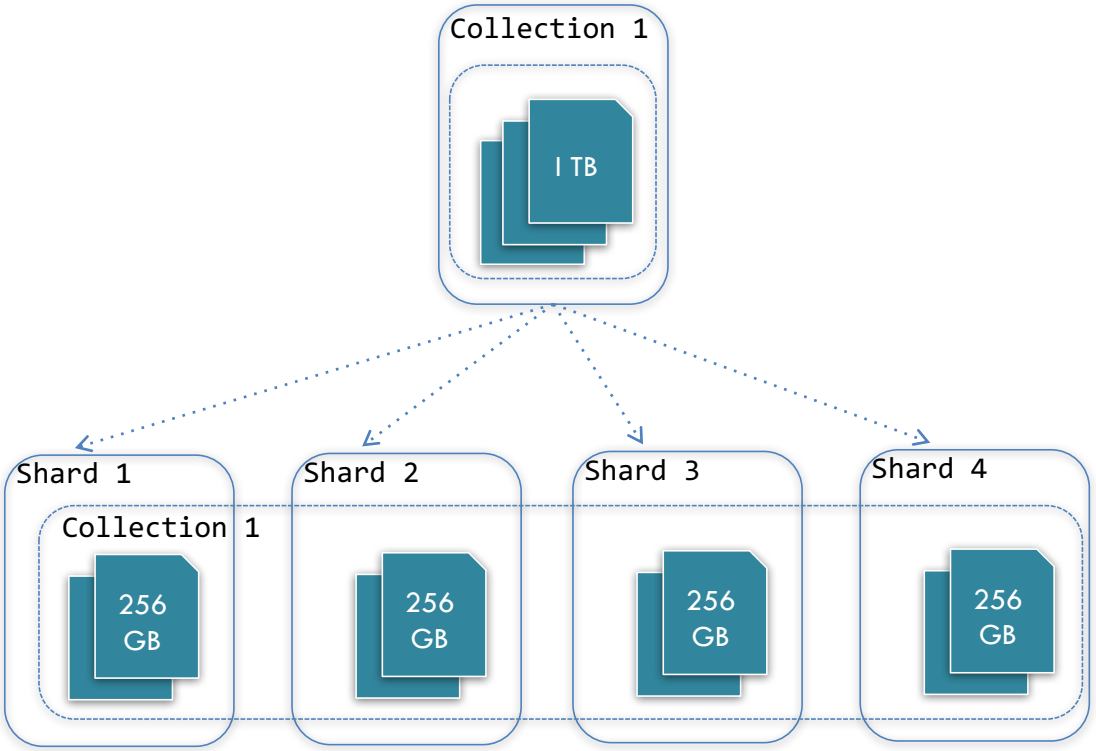
Database systems with large data sets and high throughput applications can challenge the capacity of a single server.

- High query rates can exhaust the CPU capacity of the server.
- Larger data sets exceed the storage capacity of a single machine.
- Finally, working set sizes larger than the system's RAM stress the I/O capacity of disk drives.

To address these issues of scales, database systems have two basic approaches: vertical scaling and sharding

- Vertical scaling adds more CPU and storage resources to increase capacity.
  - Scaling by adding capacity has limitations: high performance systems with large numbers of CPUs and large amount of RAM are disproportionately more expensive than smaller systems.
  - Additionally, cloud-based providers may only allow users to provision smaller instances.
  - As a result there is a practical maximum capability for vertical scaling.
- Sharding, or horizontal scaling, divides the data set and distributes the data over multiple servers, or shards.
  - Each shard is an independent database,
  - Collectively, the shards make up a single logical database

SHARDING DATA



SHARDING

Addresses the challenge of scaling to support high throughput and large data sets

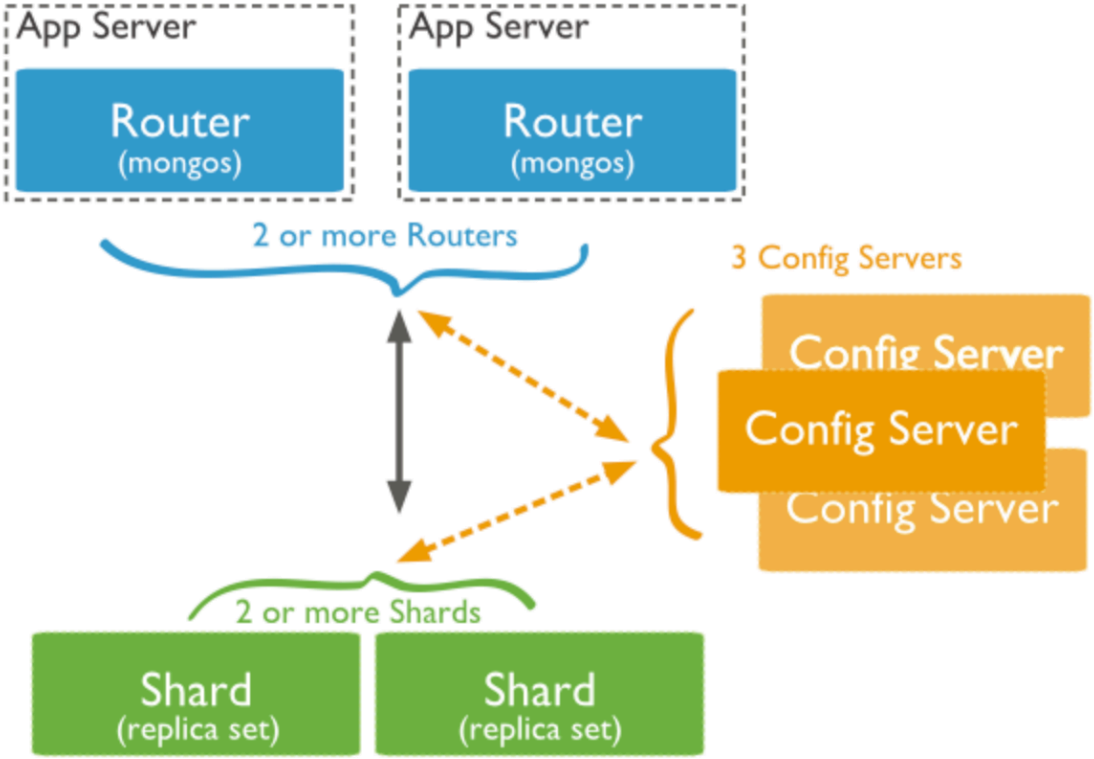
Reduces the number of operations each shard handles

- Each shard processes fewer operations as the cluster grows.
- As a result, a cluster can increase capacity and throughput horizontally
- For example, to insert data, the application only needs to access the shard responsible for that record

Reduces the amount of data that each server needs to store

- Each shard stores less data as the cluster grows.
- For example, if a database has a 1 terabyte data set, and there are 4 shards, then each shard might hold only 256GB of data. If there are 40 shards, then each shard might hold only 25GB of data.

SHARDING IN MONGODB



SHARDING IN MONGODB

Shards (mongd) store the data. To provide high availability and data consistency, in a production sharded cluster, each shard is a replica set.

Query Routers (**mongos** instances), interface with client applications and direct operations to the appropriate shard or shards.

- The query router processes and targets operations to shards and then returns results to the clients.
- A sharded cluster can contain more than one query router to divide the client request load.
- A client sends requests to one query router. Most sharded clusters have many query routers.

Config servers store the cluster's metadata.

- This data contains a mapping of the cluster's data set to the shards.
- The query router uses this metadata to target operations to specific shards.
- Production sharded clusters have exactly 3 config servers

PRIMARY SHARD

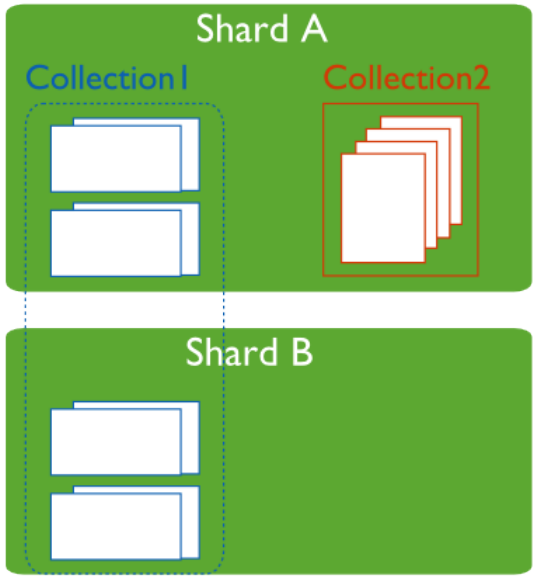
Every database has a “primary” shard that holds all the un-sharded collections in that database

To change the primary shard for a database, use the `movePrimary` command.

- The process of migrating the primary shard may take significant time to complete, and you should not access the collections until it completes.

When a new sharded cluster is deployed with shards that were previously used as replica sets, all existing databases continue to reside on their original shard

Databases created subsequently may reside on any shard in the cluster



CONFIG SERVERS

Special mongod instances that store the metadata for a sharded cluster.

Use a two-phase commit to ensure immediate consistency and reliability.

Do not run as replica sets.

All config servers must be available to deploy a sharded cluster or to make any changes to cluster metadata.

A production sharded cluster has exactly three config servers

- For testing purposes you may deploy a cluster with a single config server
- But to ensure redundancy and safety in production, you should always use three.

CONFIG DATABASE

Config servers store the metadata in the config database. The mongos instances cache this data and use it to route reads and writes to shards

MongoDB only writes data to the config server in the following cases:

- To create splits in existing chunks.
- To migrate a chunk between shards.

MongoDB reads data from the config server data in the following cases:

- A new mongos starts for the first time, or an existing mongos restarts.
- After a chunk migration, the mongos instances update themselves with the new cluster metadata.
- MongoDB also uses the config server to manage distributed locks.

DATA PARTITIONING

MongoDB distributes data, or shards, at the collection level.

Sharding partitions a collection's data by the shard key.

A shard key is either an indexed field or an indexed compound field that exists in every document in the collection.

MongoDB divides the shard key values into chunks and distributes the chunks evenly across the shards.

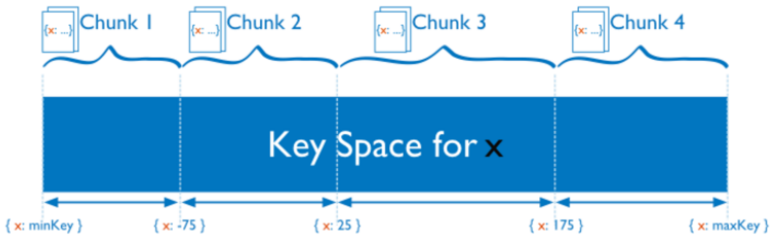
- range based partitioning or hash based partitioning

RANGE BASED SHARDNIG

MongoDB divides the data set into ranges determined by the shard key values

- Consider a numeric shard key: If you visualize a number line that goes from negative infinity to positive infinity, each value of the shard key falls at some point on that line.
- MongoDB partitions this line into smaller, non-overlapping ranges called chunks
- chunk is range of values from some minimum value to some maximum value.

Given a range based partitioning system, documents with “close” shard key values are likely to be in the same chunk, and therefore on the same shard

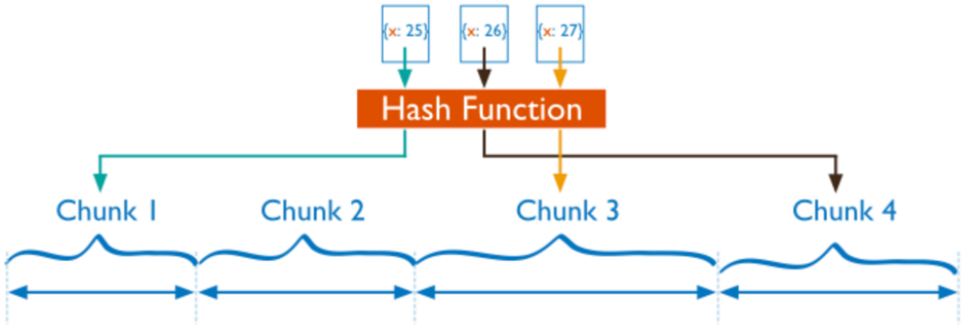


HASH BASED SHARDING

For hash based partitioning, MongoDB computes a hash of a field's value, and then uses these hashes to create chunks

With hash based partitioning, two documents with "close" shard key values are unlikely to be part of the same chunk.

This ensures a more random distribution of a collection in the cluster



TAG AWARE SHARDING

MongoDB allows administrators to direct the balancing policy using tag aware sharding.

Administrators create and associate tags with ranges of the shard key

Assign those tags to the shards.

The balancer migrates tagged data to the appropriate shards and ensures that the cluster always enforces the distribution of data that the tags describe

- Tags are the primary mechanism to control the behavior of the balancer and the distribution of chunks in a cluster.
- Most commonly, tag aware sharding serves to improve the locality of data for sharded clusters that span multiple data centers

RANGE & HASH BASED SHARDING

Range based partitioning supports more efficient range queries

- Given a range query on the shard key, the query router can easily determine which chunks overlap that range and route the query to only those shards that contain these chunks
- It can result in an uneven distribution of data, which may negate some of the benefits of sharding
  - If the shard key is a linearly increasing field, such as time, then all requests for a given time range will map to the same chunk, and thus the same shard.
  - In this situation, a small set of shards may receive the majority of requests and the system would not scale very well

Hash based partitioning, ensures an even distribution of data

- Hashed key values results in random distribution of data across chunks and therefore shards.
- Random distribution makes it more likely that a range query on the shard key will not be able to target a few shards but would more likely query every shard in order to return a result

MAINTAINING A BALANCED DISTRIBUTION

The addition of new data or the addition of new servers can result in data distribution imbalances within the cluster

- particular shard contains significantly more chunks than another shard
- a size of a chunk is significantly greater than other chunk sizes

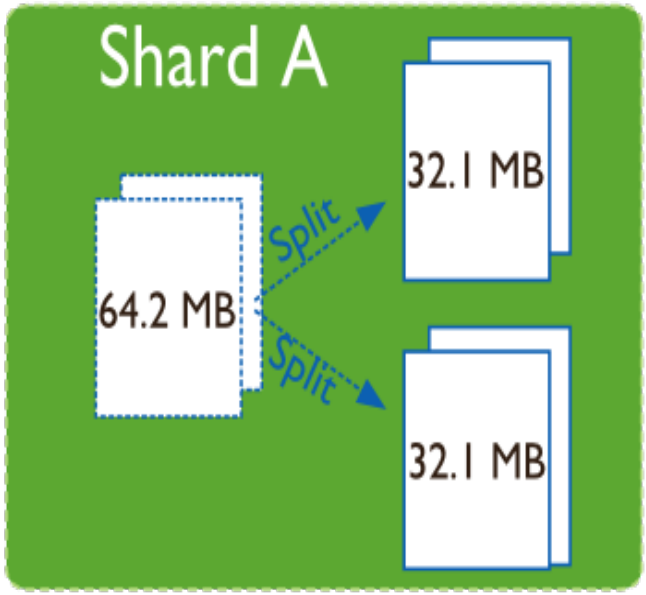
MongoDB ensures a balanced cluster using two background process: **splitting** and the **balancer**

SPLITTING

Background process that keeps chunks from growing too large.

When a chunk grows beyond a specified chunk size,

- MongoDB splits the chunk in half
- Inserts and updates triggers splits.
  - Splits are an efficient meta-data change.
  - To create splits, MongoDB does not migrate any data or affect the shards



BALANCING

The balancer is a background process that manages chunk migrations.

Runs from any of the query routers in a cluster

When the distribution of a sharded collection in a cluster is uneven

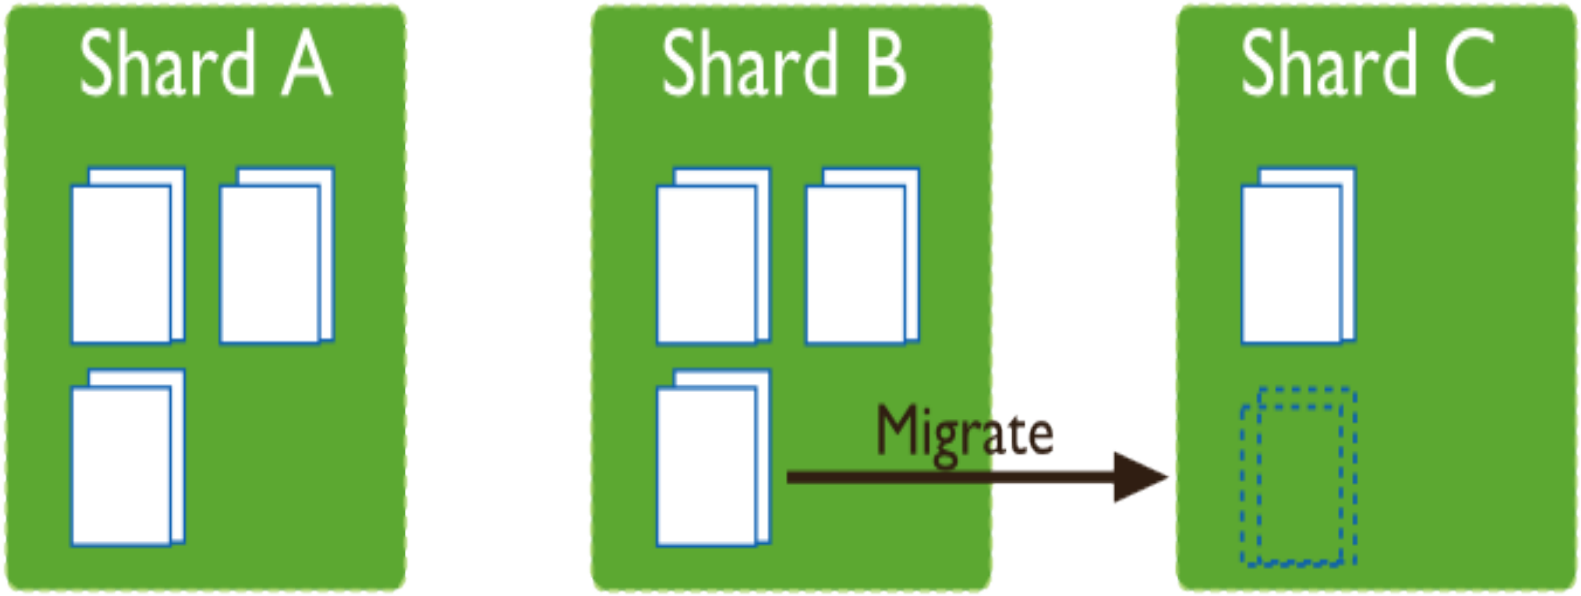
- The balancer process migrates chunks from the shard that has the largest number of chunks to the shard with the least number of chunks until the collection balances
- For example: if collection users has 100 chunks on shard 1 and 50 chunks on shard 2, the balancer will migrate chunks from shard 1 to shard 2 until the collection achieves balance

BALANCING (2)

The shards manage chunk migrations as a background operation between an origin shard and a destination shard.

- During a chunk migration, the destination shard is sent all the current documents in the chunk from the origin shard.
- Next, the destination shard captures and applies all changes made to the data during the migration process.
- Finally, the metadata regarding the location of the chunk on config server is updated
- If there's an error during the migration, the balancer aborts the process leaving the chunk unchanged on the origin shard.
- MongoDB removes the chunk's data from the origin shard after the migration completes successfully

BALANCING (3)



ADDING & REMOVING SHARDS FROM A CLUSTER

Adding a shard to a cluster creates an imbalance since the new shard has no chunks.

- MongoDB begins migrating data to the new shard immediately
- It can take some time before the cluster balances.

When removing a shard, the balancer migrates all chunks from a shard to other shards.

After migrating all data and updating the meta data, you can safely remove the shard

SHARDING VS HORIZONTAL PARITIONING

Horizontal partitioning splits one or more tables by row, usually within a single instance of a schema and a database server.

- Reduce index size (and thus search effort) provided that there is some obvious, robust, implicit way to identify in which table a particular row will be found, without first needing to search the index,
- e.g., the classic example of the '`CustomersEast`' and '`CustomersWest`' tables, where their zip code already indicates where they will be found

Sharding goes beyond this: it partitions the problematic table(s) in the same way, but across potentially multiple instances of the schema

- Search load for the large partitioned table can now be split across multiple servers (logical or physical), not just multiple indexes on the same logical server
- Splitting shards across multiple isolated instances requires more than simple horizontal partitioning
- Sharding splits large partitionable tables across the servers, while smaller tables ***are replicated as complete units***
